{kevinliu, scleong, bez, ancl}@andrew.cmu.edu

Abstract—In the field of SLAM, vision and LIDAR based SLAM systems have been increasingly popular over the recent years. While these systems achieve impressive results in outdoor environments in typical weather, these sensors often fail in more adverse environmental conditions such as rain, snow and fog. RadarSLAM[1], [2] is a Radar-based SLAM which takes advantage of Radar’s greater robustness in extreme weather conditions to address these shortcomings of previous SLAM systems. We aim to create the first open-source implementation of the current state-of-the-art RadarSLAM by Hong, Petillot and Wang [1], focusing specifically on the odometry component of RadarSLAM with additional improvements to the original algorithm. Due to the robustness to weather implications of our project, we name it Really Adverse Weather Radar Odometry and Mapping (RAW-ROAM). To implement and improve Radar SLAM, we will refactor various aspects of their paper, and use ideas drawn from other radar odometry papers such as Radar Odometry using phase correlation [3] and classical computer vision methods and data structures [4], [5] in order to perform accurately and efficiently. We will evaluate our results on the Oxford Robot RadarCar dataset [6], [7], similar to that of the original paper.

Index Terms—Radar SLAM, KLT, Motion Distortion, Phase Correlation (FMT), Outlier Rejection, Loop Closure.

I. INTRODUCTION

MOST cameras and LiDAR sensors are not robust to changes in illumination, which can occur in multitudes of situations. In the case where there is low light illumination, cameras and LiDARs will have more motion blur, noises, and losses of texture [2]. Additionally, LiDARs and cameras are not invariant to situations with high concentration of dense particles, such as the fog, snow, rain, or storm conditions. In misty, rainy, or snowy weather, the density of the particles will significantly affect the point clouds generated by LiDAR and the images generated by cameras. Creating a weather-invariant SLAM system is still an active area of research, and the RAW-ROAM method is one that aims to solve such a problem.

Radar is a sensor that has the potential to combat weather adversity. Radar sensors utilize a significantly lower frequency range (GHz) as compared to LiDARs (THz to PHz). Due to this, it can penetrate more easily through particles and therefore can operate more reliably in weather conditions. It also offers a further sensor range, relative velocity estimations (from Doppler effect), etc. In recent research, radar sensing has also shown the application of creating dense maps rather than range restricted maps, which further increases its viability. Radar is therefore a prime choice in combating weather adverse conditions where other sensors fail.

However, radar brings many challenges, including significantly lower resolution and higher signal-to-noise ratio com-

pared to traditional sensors. Moreover, its sensing patterns, geometry, and data formation is all very different from vision and LiDAR. This means that robust feature detection algorithms used in other sensors cannot be directly applied to radar data, and intermediate steps have to be taken to clean up the data from radar-specific sensing problems, such as radar motion distortion.

RadarSLAM [1], [2] describes a full pipeline that uses radar data to generate mapping and odometry information. We aim to reimplement and possibly improve upon the RadarSLAM algorithm, focusing specifically on the odometry and mapping components (i.e. RAW-ROAM).

II. CONTRIBUTIONS

As of the paper’s creation, no other open-source implementation of RadarSLAM has been made available. While parameters from the paper have been released to allow for reimplement, the lack of an implementation of this contemporary method will be troublesome to future researchers in the field. As such, we aim to make available **the first open-source implementation** of RAW-ROAM odometry to give insight into RadarSLAM and its viabilities. Additionally, the 2020 and 2021 papers describe similar but different methodologies to create the radar odometry pipeline. We will combine the 2020 and 2021 Radar SLAM papers[1], [2] to try to reimplement and improve upon the RadarSLAM odometry algorithm.

III. ALGORITHM

Our pipeline consists of 3 main parts: feature extraction, odometry and local mapping, as well as a partially complete loop closure thread as shown in Figure 1 below:

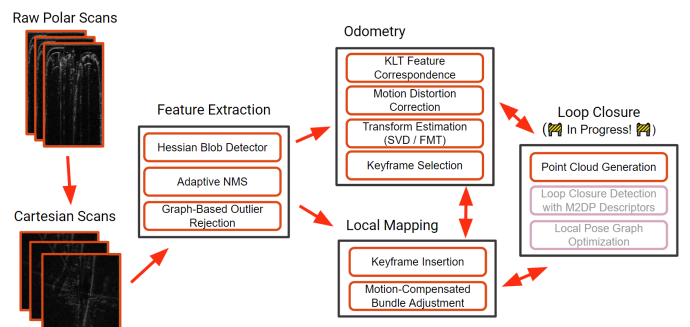

Fig. 1: Visual Overview of Pipeline

A. Input Data and Coordinate Conversion

In a 360-degree radar scan, the sensor sends out numerous azimuth scans and waits for echos as the beams bounce off of objects in the environment, as shown in Figure 3 below. A raw polar image in azimuth and range units can be converted into a Cartesian image using bilinear interpolation. This is done using OpenCV's `warpPolar()` function. Note that elevation information such as object height is thrown out and the data is collapsed into a single 2D image along a flat plane. Due to the decreasing accuracy of radar with increasing range, we cropped out information from radar scans at a distance greater than 87.5 meters, as per the paper's parameters [2].

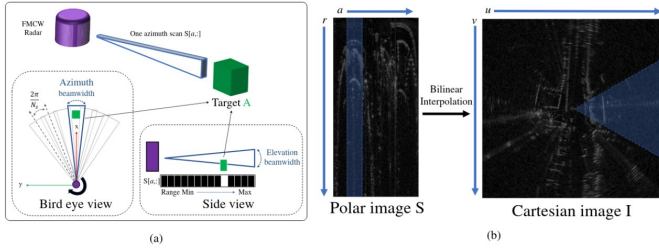

Fig. 2: Radar scanning operation, and log-polar and Cartesian representations of the radar image. Taken from [2]

B. Feature Selection

In these Cartesian radar scans, a small patch of higher response corresponds to a detected object. Feature points can thus be extracted efficiently via a basic Blob Detector using a Determinant of Hessian Method [2]. The blob detector will be able to extract homogeneous areas, or in our case, large significant areas of static and dynamic obstacles. This approach locates maximas in the Determinant of Hessian of the radar image and is computed using box filters instead of convolutions as is the method when using the alternate Laplacian of Gaussian (LoG) or Difference of Gaussian (DoG) approaches to blob detection, which allows it to be much more efficient.

We found the DoH to be the fastest and most robust of the three approaches as it performs equally to DoG and LoG in suppressing the responses of small specks in the radar image that could be the result of radar noise, while performing much faster. We further thresholded the candidate points by their Hessian response. The parameters we used can be seen in Table I below:

TABLE I: Determinant of Hessian (DoH) Blob Detector Parameters

Parameter	σ_{\min}	σ_{\max}	σ_{num}	$f_{\text{threshold}}$
Value	1	30	10	0.1

These points are further pruned using an adaptive non-maximal suppression (ANMS) approach to create a set of points which are spatially distributed evenly across the entire radar image while retaining the most relevant ones [4]. This allows us to discard many redundant feature points clustered

together from our blob detector and set the number of points we want. In our implementation, we adopt a suppression via Square Covering (SSC) implementation of ANMS from [4]. We find that ANMS filtering is able to drastically reduce the number of tracked feature points, and only keep up to the number of points we want.

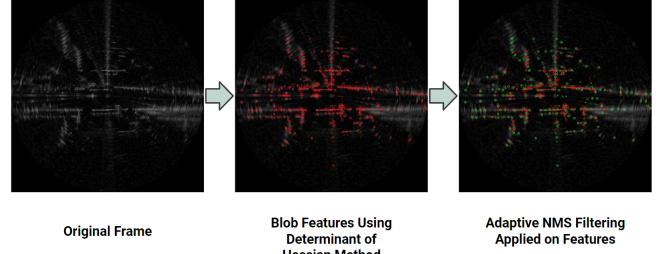

Fig. 3: Feature detection performed using blob features using DoH method compared with the original frame and post ANMS result. The red points are the detected blob features, the green points are the selected ANMS features

C. Feature Tracking

We utilize a Kanade–Lucas–Tomasi (KLT) tracker, a fast method commonly used in visual odometry, to find correspondences of sparse feature points. Given an initial radar scan, subsequent Cartesian radar scans, and a set of blob features on the initial scan, KLT iteratively predicts optical flow of the blob features from the initial frame to the subsequent frames. It uses image gradients on the radar scans to identify potential matching blobs between the scans. It then minimizes the residual difference of the returned point correspondences and their 2D neighborhoods to achieve local tracking. We use the OpenCV implementation of KLT, which exploits image pyramids [8] and RANSAC to further improve the performance of the operation in the event of large rotations or translations.

D. Relative Transformation Calculation

Consider the cartesian frame A and the subsequent frame B along with the set of n correspondences between them. We are able to estimate the movement of the robot during this period by using a SVD-based approach [9]:

$$\mathbf{p}_A = \{\mathbf{p}_A^i | i \in [n]\} \quad \mathbf{p}_B = \{\mathbf{p}_B^i | i \in [n]\}$$

We want to find the unknown transformation matrices R, t to find, and their relation $\mathbf{p}_B = R \cdot \mathbf{p}_A + t$. We then construct the matrix H and find its singular value decomposition:

$$H = (\mathbf{p}_A - \text{centroid}_{\mathbf{p}_A})(\mathbf{p}_B - \text{centroid}_{\mathbf{p}_B})^\top \\ U, S, V = \text{SVD}(H)$$

Then, we obtain the rotation and translation as follows:

$$R = UV^\top \quad t = \text{centroid}_{\mathbf{p}_B} - R \cdot \text{centroid}_{\mathbf{p}_A}$$

Note that in the above procedure, we may need to deal with the case that R has a negative determinant. This special reflection case is explained in [9].

This result is a rotation matrix R and translation vector t of blobs across corresponding radar frames in pixels. Using the intrinsic parameters of our radar sensor such as the range resolution, we are able to convert this transform into the ego movement of the robot in the world frame. By computing this transformation between all consecutive frames, we are able to integrate the trajectory of the robot over the course of the entire sequence.

Note that in this setup, KLT may fail to find good point correspondences for certain feature points in the previous frame. This may be due to noise, occlusion, or typically an object moving out of sensor range and are subsequently discarded and not included in the set of correspondences. However, in order to maintain a healthy set of feature points for tracking, we replenish them if the number of features falls below a threshold `min_num_features = 80`.

E. Graph-Based Outlier Rejection

Ideally, we want to only track static features like roads, lamp-posts, trees and signages, instead of dynamic features such as moving cars, pedestrians and cyclists. Unlike in the case of camera images or 3D LiDAR point clouds, the unique birds-eye-view geometry that the radar sensor affords us enables the pruning away of dynamic outliers. This is because static features in a 2D birds-eye-view must satisfy the rigid-body constraint across frames: for any 2 arbitrary (static) points, the distance between them must be the same between frames. Therefore, to find out whether a point satisfies this constraint, we use a graph-based method as follows.

With feature correspondences \mathbf{p}_A and \mathbf{p}_B , we are able to form an unweighted graph \mathcal{G} whose nodes are the corresponding feature points from the above set. We then form an adjacency matrix, connecting 2 arbitrary nodes i and j together if only they satisfy the following constraint:

$$\|\mathbf{p}_A^i - \mathbf{p}_B^i\|_2^2 - \|\mathbf{p}_A^j - \mathbf{p}_B^j\|_2^2 < \epsilon$$

where the value of ϵ used in our implementation is 0.5 meters.

In other words, we only connect 2 nodes (points) if the Euclidean distance between them in frame A is “close enough” to the distance in frame B. The inlier set is therefore the set of nodes (points) which are still connected to the other nodes in \mathcal{G} , and finding this inlier set is equivalent to finding the maximum clique of \mathcal{G} [1], [2]. In code, this is solved efficiently using the Python `networkx` library.

Figure 4 below visualizes how the graph-based outlier rejection works. The object in dark red is a moving outlier and fails to satisfy the rigid-body constraint, unlike the feature points shown as the green boxes. As visualized in the figure, these green boxes will form a clique with each other in graph \mathcal{G} .

Figure 5 below shows a real example of outlier rejection working to remove dynamic outliers, including moving features (eg. moving cyclist or pedestrian) and radar sweep errors (eg. multipath, noise).

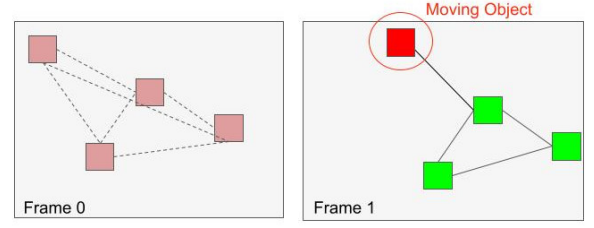

Fig. 4: Visualization of graph formed in outlier rejection

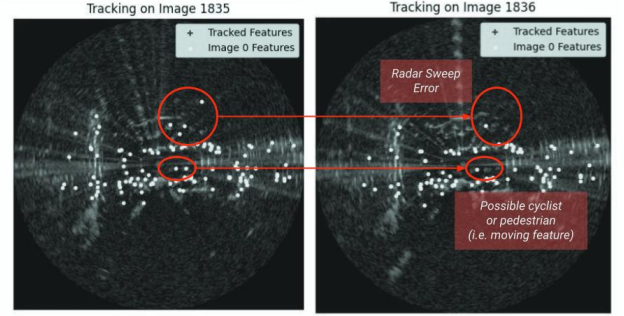

Fig. 5: Example of outlier rejection working on real data

This graph-based outlier rejection is extremely effective and key to ensuring that only static features are tracked for a robust odometry estimate. Tests show that an average 28% of feature points are removed using this algorithm.

F. Rotation Correction with Fourier-Mellin Transform (FMT)

As noted in the paper [2], KLT sometimes fails to track properly when rotations are large. To resolve this problem, we present a novel contribution to correct for rotations before applying KLT, using the Fourier Mellin Transform (FMT) as used in [3] to get an initial estimate for rotation. In summary, we first convert the radar image into log-polar space, and perform phase correlation to obtain the relative translation in the log-polar domain, which corresponds to a change in angle (rotation) and scale. We followed the suggestions in the paper to downsample only in the radial direction to save on memory and computation while keeping precise angular resolution. However, we also additionally cropped the image using the maximum range value specified in the RadarSLAM paper [2] because we were finding that the long multipaths in the uncropped image were significantly throwing off the rotation estimates in the FMT algorithm. Figure 6 below shows an example of rotation correction using the FMT algorithm. Currently, this feature is turned off for the sequence we are testing on because the algorithm works fine without it, but might come in useful in situations where relative rotations are more severe (e.g. with sharper turns).

G. Keyframe Selection

In order to reduce memory requirements, especially for real-world large-scale systems, we do not log the pose and map

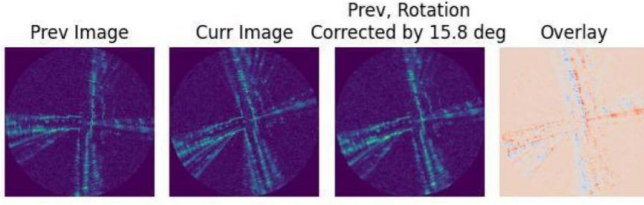

Fig. 6: Example of Fourier Mellin transform correctly accounting for large rotations

point information for every frame to be used for local mapping and bundle adjustment. Instead, we choose *keyframes*, which contain pose information and feature points (from **Feature Selection**) to be used as map points. A frame \mathcal{F} is selected as a keyframe if it matches any of the following criteria [1]:

- First frame of sequence
- Euclidean distance (relative position) between the previous keyframe, \mathcal{K} , is less than threshold δ_d :

$$\|\mathcal{F}_{(x,y)} - \mathcal{K}_{(x,y)}\|_2 < \delta_d$$

- Rotation (relative orientation) between the previous keyframe, \mathcal{K} , is less than threshold δ_θ :

$$|\mathcal{F}_\theta - \mathcal{K}_\theta| < \delta_\theta$$

- Number of map points in \mathcal{F} is below the `min_num_features` threshold used in Section III-B above.

The parameters used in the code are shown in Table II below.

TABLE II: Keyframe Selection Parameters

Parameter	δ_d	δ_θ	<code>min_num_features</code>
Value	2 m	0.2 rad	80

H. Motion-Compensated Bundle Adjustment

1) Motion Distortion

When using the radar sensor, which operates at relatively low frequencies (4Hz for our dataset) compared to LiDAR and cameras, we must compensate for the movement of the robot during the course of each scan. As aforementioned, the mechanical scanning radar takes numerous azimuth scans as it rotates a full 360-degrees. During the course of a full 360-degree scan, a high speed vehicle could have traveled multiple meters and degrees meaning that each azimuth scan could have been taken from a different position and orientation in space.

In reconstructing these 2D radar scans, we assumed that the robot was stationary, however this assumption results in severe motion distortion as visualized in Figure 7. This phenomenon is especially evident during sequences in which the robot is turning as this adds or subtracts from the absolute rotation of the rotating radar scanner. As a result, motion distortion is responsible for a great deal of drift when doing pure dead reckoning as seen in Figure 8 below.

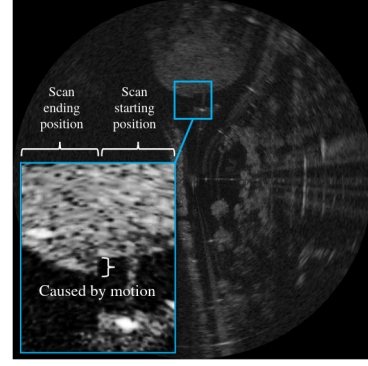

Fig. 7: Example of motion distortion, taken from [2]

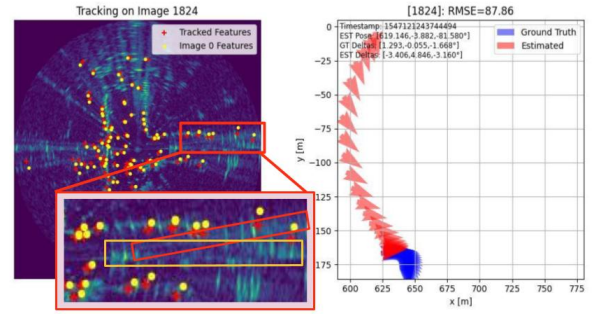

Fig. 8: Motion distortion on real data affecting estimates during turns.

To account for motion distortion, the velocity of the vehicle is explicitly modeled to compensate for the distortion in odometry [2]. Suppose that a full radar scan \mathcal{S}_j takes time Δt to complete. Suppose also that the vehicle has a velocity vector $\vec{v}_j = [v_x \ v_y \ v_\theta]^\top$ for the period of this scan. Then, for the time range of azimuth scans $t \in [-\Delta t/2, \Delta t/2]$, the pose of the robot in the scan frame can be modelled as:

$$\mathbf{p}_{j_t} = \begin{bmatrix} x_t \\ y_t \\ \theta_t \end{bmatrix} = \begin{bmatrix} v_x t \\ v_y t \\ v_\theta t \end{bmatrix}$$

$$\mathbf{T}_{j_t}^j = \begin{bmatrix} \cos \theta_t & -\sin \theta_t & x_t \\ \sin \theta_t & \cos \theta_t & y_t \\ 0 & 0 & 1 \end{bmatrix} = \begin{bmatrix} \cos(v_\theta t) & -\sin(v_\theta t) & v_x t \\ \sin(v_\theta t) & \cos(v_\theta t) & v_y t \\ 0 & 0 & 1 \end{bmatrix}$$

where $\mathbf{T}_{j_t}^j$ is the pose of the robot in the scan frame (j) in “homogeneous matrix form”, and can also be thought of as the operation to “undistort” a motion-distorted point.

If we denote \mathbf{T}_j^w as the transformation from the scan frame to the world frame (w), obtained directly from odometry estimates as per Section III-D, then we can effectively obtain our motion-compensated robot pose at scan time t as:

$$\mathbf{T}_{j_t}^w = \mathbf{T}_j^w \mathbf{T}_{j_t}^j$$

In the same vein, if the i^{th} keypoint \mathbf{q}_w^i in the world frame is observed as $\mathbf{q}_{j_t}^i$ in the azimuth scan at time t , then its motion compensated location (j_0) in the scan frame is [2]:

$$\mathbf{q}_{j_0}^i = \mathbf{T}_{j_t}^j \mathbf{q}_{j_t}^i$$

2) Bundle Adjustment Optimization

We then formulate an optimization problem as in [2], which aims to minimise both the residual of the keypoint positions, e_p , and the residuals of the estimated velocity e_v simultaneously”:

$$e_p = \rho_c \left((\mathbf{T}_j^w)^{-1} \mathbf{q}_w^i - \mathbf{q}_{j_0}^i \right)$$

$$e_v = \vec{\mathbf{v}}_j - \vec{\mathbf{v}}_{prior}$$

where ρ_c is the Cauchy robust cost function, and $\vec{\mathbf{v}}_{prior}$ is the estimated velocity between frames (relative pose divided by Δt), obtained from the relative pose of the keypoints. The initial conditions for both \mathbf{q}^i and $\vec{\mathbf{v}}_{prior}$ are obtained from naive KLT tracking, as explained in Section III-D above.

This “velocity” residual term is important to regularize the velocity value fitted. Hong, Petillot and Wang showed that when the fitted velocity term is allowed to be an arbitrary value, the odometry results were poor. This error term ties the fitted velocity term to the fitted transform term, such that both values were mutually consistent. Moreover, the velocity estimate is dependent on the incorrect estimates of keypoint positions which we are trying to optimize for, and so both the keypoint positions and velocity need to be optimized together.

It is noted that here we are effectively performing motion-distortion-compensated bundle adjustment by obtaining better estimates of (local) map points and robot poses using a motion model. The optimization is solved by the Levenberg–Marquardt algorithm, and our implementation uses the `scipy` solver library to do so.

I. Mapping

Mapping is done implicitly using feature points from **Feature Selection** in the keyframe from **Keyframe Selection**. Figure 9 below shows a partial map using subsampled feature points from frames 2100 to 2500.

IV. EXPERIMENTS AND RESULTS

We quantitatively and qualitatively evaluated the performance of RAW-ROAM using the Oxford RobotCar dataset which includes sequences that occur in varying weather conditions. To evaluate the pose estimation accuracy, we compute the Root Mean Square Error (RMSE) between the ground truth and estimated position at each frame.

Due to time constraints, we were only able to run tests on a single sequence. **This sequence** had a car mounted with a 4Hz Navtech CTS350-X Radar traveling 9.02 km over the course of 37 minutes. To process the 8864 frames of this sequence, including generating the video, requires around 2-3 hours on a consumer laptop running a i7-8650U processor without a GPU. Part of the reason why the algorithm takes so long is likely to be due to the fact that it is written in Python instead

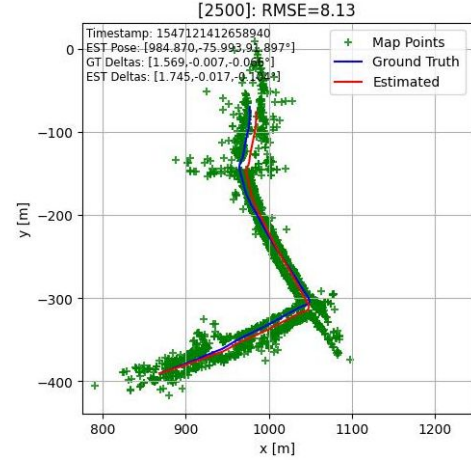

Fig. 9: Partial map of frames 2100 to 2500 of Oxford-10-11-46-21

of C++, and also because image writing operations are being performed to generate visualizations.

Seen in Figure 10 is the estimated trajectory computed by RAW-ROAM with pure dead reckoning and outlier rejection, but without motion distortion correction. Note that due to the lack of motion distortion correction, the estimated trajectory sees a great deal of drift during turns. The lack of loop closure means the the drift accumulates exponentially over the course of the entire trajectory. However, in regions with minimal rotation such as straight roads, RAW-ROAM performs well.

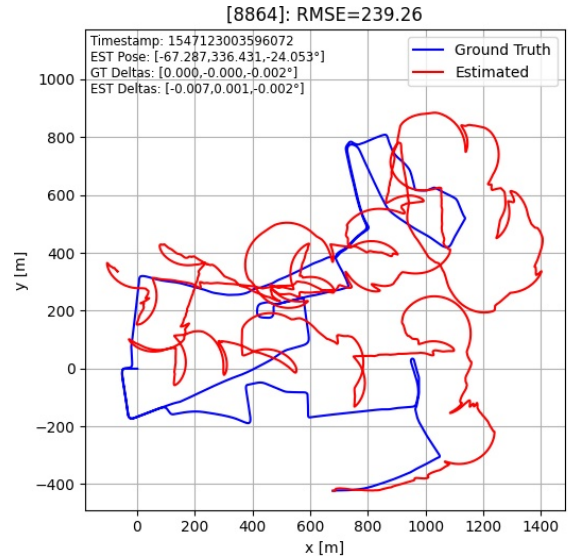

Fig. 10: Estimated trajectory on Oxford-10-11-46-21 without motion distortion correction

Seen below in Figure 11 is the estimated trajectory with motion distortion correction enabled. The trajectory is far more accurate to the ground truth trajectory. The odometry performs well during turns and although it noticeably drifts from the ground truth, the improvement is clear. With loop closure implemented, we could predict that a future system could correct for this drift and achieve similar performance to

RadarSLAM.

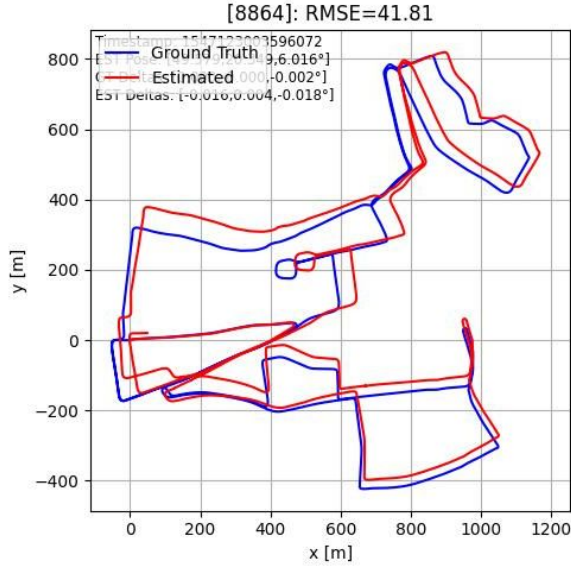

Fig. 11: Estimated trajectory on Oxford-10-11-46-21 with motion distortion correction

V. COMPARISON WITH RADARSLAM

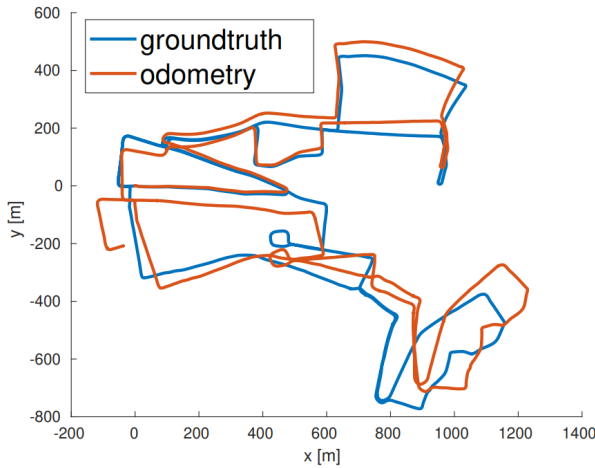

Fig. 12: RadarSLAM's odometry on the same Oxford Robot Car dataset after correcting for motion distortion [2]. Note that we use a different convention in plotting the trajectory causing them to be vertically flipped with respect to each other.

Figure 12 shows the result obtained by Hong, Petillot and Wang in their 2021 RadarSLAM system. Qualitatively, our odometry shows comparable if not better performance on the dataset. RadarSLAM's odometry error was quantified as 2.16% translation error and 0.6°/100m rotation error for the same sequence on the Oxford dataset, which is difficult to compare against our RMSE metric. Assuming the 2.16% is a ratio of the total distance traveled. The dataset distance of 9 km yields an error of 180m translational error. That being

said, the paper does report an RMSE of 13.784 for SLAM but that is including loop closure. In comparison, our odometry RMSE without loop closure is 41.81, which is quite good for dead-reckoning odometry, but could of course be improved had we implemented the loop closure component.

VI. FUTURE WORK

Because of time constraints and issues with the `g2o` library, we were unable to get pose graph optimization and loop closures working. However, the code base for generating the point clouds and M2DP descriptors [10] required for the loop closure portion of the pipeline is in our repository, and other people would be able to build from it if they want to.

We also have not attempted to design the system for real-time application. There are various gains to be made from dual-threading, further vectorization and toolset changes that could bring the system's performance in line with the original RadarSLAM's frame-rate performance. RAW-ROAM runs offline and should not be evaluated as a real-time tool.

APPENDIX

A. Videos

Videos of our visualizations, including several full length radar sequences, can also be found on Google Drive [here](#).
